COMPLETE SPECIFICATION

Process of Depositing Silica Films

We, RADIO CORPORATION OF AMERICA, a Corporation organized under the Laws of the State of Delaware, United States of America, of 30, Rockefeller Plaza, City and State of New York, United States of America, do hereby declare the nature of this invention and in what manner the same is to be performed, to be particularly described and ascertained in and by the following statement:—

This invention relates to the art of depositing thin, transparent films of silica on a surface.

Thin films of silica have proved useful in the art for providing reflection-reducing surfaces on optical elements made of glass as well as in the protection of more chemically active substances from the corrosive effects of the atmosphere and other surrounding media. Heretofore, various methods have been proposed for the deposition of these silica films. One of these has been an adaptation of the well known vapour coating method in which quartz is heated to a temperature high enough to vaporize the silica. Because of the extremely high temperature at which silica vaporizes, however, this is a costly and difficult method to use. It has also been proposed to deposit silica from organic silicates, alkali silicates and from the vapour of decomposable silicon compounds such as silicon tetrachloride. Although these methods have been more or less successful for some commercial applications, it has proved to be very difficult to deposit an even film of silica having an accurately controlled thickness by any of these older methods.

One object of the present invention is to provide an improved method of depositing very thin films of silica having accurately controlled thicknesses.

Another object is to provide a method of depositing transparent films of silica with the expenditure of very little mechanical energy.

Another object is to provide an

improved method of protecting glass surfaces with thin, silica films. 50

Another object is to provide an improved method of depositing silica from a solution.

Still another object is to provide an improved method of depositing reflection-reducing films of silica on transparent optical surfaces. 55

These and other objects will become more apparent and the invention will be better understood from a study of the description of the invention which follows together with the accompanying drawings, of which:

Figure 1 is a graph showing the rate of deposition of a silica film deposited 65 from a typical treating bath made up according to the present invention. Thickness in λ at 5200\AA is shown as function of time of treatment (hours).

Figure 2 is a graph showing the time 70 necessary to deposit a $\frac{1}{4}$ wavelength film from fluosilicic acid solutions adjusted to various degrees of supersaturation with respect to silica. Minutes to deposit

λ film is shown as a function of centi- 75 4

meter cubes of 4% boric acid/litre of acid.

Figure 3 is a graph of the change in excess silica solubility with concentration of H_2SiF_6 , taking a 1.25 molar solution of H_2SiF_6 as a zero reference point. 80 Silica moles is shown as a function of H_2SiF_6 moles per litre.

It has been found that a solution of fluosilicic acid supersaturated with just the correct amount of silica will deposit 85 a very thin, uniform, hard, transparent film of silica upon an object immersed in the solution. This is in contrast to a fluosilicic acid solution which is either just saturated or undersaturated with silica since these latter types attack most glasses slowly instead of depositing silica on them and, of course, do not deposit silica on other surfaces immersed in them. The 90

method of the present invention is also in contrast to the method of skeletonizing the surface of a glass article in order to produce a reflection reducing film. The 5 skeletonizing process also utilizes a solution of fluosilicic acid supersaturated with respect to silica but the range of super saturation is somewhat different in the two cases. The close similarity 10 between the two types of solution, however, serves to indicate the fine degree of control necessary to obtain films according to the present invention and the unexpectedness of the results obtained in 15 the process.

Of course, one general method of depositing a substance chemically is to supersaturate a solution with respect to the substance, then introduce conditions 20 which will cause the excess substance to precipitate out of the solution. This general method can also be used to obtain a deposit of silica as is well known. However, as is equally well known, the deposit 25 of silica which is usually formed is a gelatinous mass which is of a cloudy or translucent nature. By practising the method of the present invention, an optically thin film may be formed which 30 is hard and transparent. This film may be controlled so accurately as to be of the order of $\frac{1}{4}$ wavelength in thickness of some desired component of white light or it may be much thicker in order better to serve 35 as a protective coating. If it is to be used as a reflection reducing film, it may be made, as is well known, a small, odd multiple of $\frac{1}{4}$ wavelength in thickness.

The method according to the present 40 invention is performed by immersing the article to be coated in a solution of fluosilicic acid which has been made supersaturated with respect to silica within the range of 2 to 16 millimoles per 45 litre. A preferred range of excess silica is 8 to 15 millimoles per litre and a preferred point within this range is 10 millimoles of supersaturation per litre. The fluosilicic acid appears to act as a catalyst 50 in the deposition of the silica.

The method of making up the treating 55 solutions can be accomplished in several ways. It must first be pointed out that, although fluosilicic acid is generally described in the literature as conforming with the ideal formula H_2SiF_6 , it has been found unexpectedly that commercial fluosilicic acid is capable of dissolving considerable excess silica so that the final 60 stable solution obtained has a ratio of fluorine to silica of nearer 5 to 1 on a gram equivalent basis than the 6 to 1 indicated by the theoretical formula. This saturated solution is obtained by taking 65 commercial fluosilicic acid and dissolving

in it all the silica it will take at 25° C. Actually, the fluosilicic acid is allowed to remain in contact with solid reagent silicic acid for an hour or two in order to put in the added amount of silica. This saturated 70 solution is then made supersaturated to the required degree. In order to do this, a reagent which increases the amount of silica available for deposition may be added to the saturated solution. The 75 saturated solution may be simply diluted with water, or boric acid may be added to reduce the solubility of the silica or sodium silicate may be added to introduce the excess silica. 80

The relative amount of silica, over and above that required by the formula H_2SiF_6 , which is present in saturated solutions of various concentrations of fluosilicic acid in moles per litre is illustrated in Figure 3. This figure is a graph of experimental results obtained using a solution containing 1.25 moles per litre of H_2SiF_6 as a zero reference point. The graph shows that as the concentration of 90 the fluosilicic acid in moles per litre rises, increasing amounts of silica are dissolved per mole of H_2SiF_6 . For example, the graph shows that a 2.5 molar solution of H_2SiF_6 will dissolve almost 12 millimoles 95 more silica per mole of H_2SiF_6 than will a 1.25 molar solution of the acid.

Specific examples of making up the treating solution follow:

EXAMPLE 1

A litre of 2.5 molar solution of fluosilicic acid is saturated with silicic acid at 25° C. This is then diluted with an equal volume of water to make up two litres of 1.25 M solution. The resulting 105 solution has now become supersaturated with silica to the extent of about 12 millimoles per mole of H_2SiF_6 or about 15 millimoles per litre of solution and deposits silica smoothly and uniformly. 110

This is so since the litre of 2.5 molar solution when diluted to form 2 litres of 1.25 molar solution still has the higher amount of silica which the 2.5 molar saturated solution was able to dissolve. 115

The curve shown in Figure 1 illustrates the rate of deposition of silica on a glass surface brought about by immersing a glass plate in this solution. As shown in the figure, a film which is $\frac{1}{4}$ wavelength 120 of green light of 5200 Å in thickness deposits in about 14 hours while one which is $\frac{1}{2}$ wavelength thick deposits in about 30 hours. The rate of deposition decreases somewhat as the time increases. 125 Thickness of deposit was determined visually from the interference colour.

In order to compare the results of diluting the 2.5 molar solution of fluo-

silicic acid saturated with silica; with varying amounts of water, samples of the base solution of Example 1 were diluted with water to give solutions containing 5 from 10 to 90% of the 2.5 M acid. Most of these dilutions did not give satisfactory films comparable with those obtained by diluting to about 50% 2.5 M acid strength since either too much or too little excess 10 silica was caused to appear in the solution. Those, with substantially greater amounts of water, being too supersaturated with respect to silica (or silicic acid) simply produced a heavy white precipitate while 15 those with substantially less water took unreasonably long periods of time although they deposited silica very slowly.

EXAMPLE 2

To a 1.4 M fluosilicic acid solution, 20 which is saturated with silica at 25° C., various amounts of boric acid were added in quantities ranging from 20—40 cc of 4% boric acid per litre of fluosilicic acid solution. The time required for amounts 25 within this range to deposit a film having a thickness of $\frac{1}{4}$ wavelength of green light of 5200 Å at 55° C. is shown in Figure 2. The addition of 20 cc of the 4% boric acid per litre of the fluosilicic acid solution 30 results in a solution supersaturated with respect to silica to the amount of 8 millimoles per litre. The 40 cc addition caused a supersaturation of 16 millimoles. When quantities of boric acid were used 35 sufficient to provide more than 16 millimoles excess silica per litre a cloudy white deposit of silica forms instead of a hard, transparent film. Amounts substantially lower than 20 cc resulted in film 40 formation only over long periods of time and no film formation at all when the amount used was such as to reduce the silica supersaturation to less than 2 millimoles per litre.

45 The examples given merely illustrate two ways in which a fluosilicic acid solution saturated with silica may be made supersaturated. Obviously, other equivalent reagents may be used. The 50 concentration of the fluosilicic acid solution is not at all critical within ordinary limits. Obviously, a solution which is unreasonably dilute is not practical because of the difficulty or even 55 impossibility of adjusting it to the correct amount of supersaturation with respect to silica while concentration above 2.5 molar cannot be obtained commercially at present.

60 The rate of deposition of silica also depends upon the temperature of the solution, the rate being more rapid at higher temperatures. When the temperature is too high, the deposit becomes 65 milky. The amount of silica needed to

supersaturate the fluosilicic acid solution to the required extent, of course, changes also with temperature. However, it has been found that the change is quite irregular and is different for different 70 molar concentrations of fluosilicic acid. It has been found, for example, that in the case of a 1.25 molar solution there is no difference in the required amount of silica between a solution at 25° C. and one at 45° C. But at other concentrations, the amount does change and for most concentrations above 1.25 molar the amount is actually less than at 25° C. But, regardless of specific concentration of the fluosilicic acid within the workable limits or of ordinary temperatures of deposition, 75 the range of supersaturation with respect to silica (or silicic acid) remains the same for the formation of good deposits within reasonable periods of time. The optimum range of temperatures to observe for good deposition has been found to be 25° C. to 80 55° C. Temperatures at least as high as 70° C. may be used at relatively low concentrations of fluosilicic acid and lower temperatures than 25° C. may be used especially when relatively high concentrations of fluosilicic acid are present. It is 85 not practical to use the higher ranges of concentration when also using higher temperatures, however, since solutions are likely to become turbid and unfit for good 90 deposition.

Films produced by deposition of silica 100 by the method described are hard and smooth. Their index of refraction is 1.46 corresponding with solid silica. They appear to deposit well on any kind of glass or other ceramic surface. On glass having 105 an index of refraction of 1.52, a $\frac{1}{4}$ wavelength film (with respect to green light of 5200 Å) has a blue interference colour and has a reflectivity only 59% of that of the clean glass with no film. While this 110 is not as great a reduction in reflectivity as that produced by some other methods due to the relatively high index of refraction of the film, the durability is excellent and the film is relatively inexpensive to 115 apply.

The films can be deposited on surfaces other than those of a ceramic nature. For example, they will form on plastics. Among those giving especially good 120 results are the urea formaldehyde and the phenolic plastics. In general, it may be said that the films can be deposited with varying degrees of excellence upon any substance not attacked by fluosilicic acid. 125 They are useful for putting a protective surface on the article which renders it comparatively immune to attacks by many corrosive liquids and atmospheric influences. 130

There has thus been described an improved method of depositing hard, transparent, silica films from a controlled solution. The films may be made so thin that they will reduce reflection from a glass surface or they may be made thick enough to serve as protective coatings on various surfaces.

Having now particularly described and ascertained the nature of our said invention, and in what manner the same is to be performed, we declare that what we claim is:—

1. A process of depositing a film of silica on a surface preferably of vitreous, ceramic, or resinous structure such as glass, a urea-formaldehyde condensation product, or the like, which consists in immersing the article to be coated in a solution of fluosilicic acid supersaturated with respect to silica to the extent of 2 to 16 millimoles of silica per litre of solution and allowing the article to remain in said solution until a coating of desired thickness has formed.

2. A process as claimed in Claim 1, according to which the excess of silica is 10 millimoles per litre.

3. A process as claimed in Claim 1, according to which the excess of silica is 15 millimoles per litre.

4. A process as claimed in any of the Claims 1 to 3, according to which the silica film is a reflection-reducing coating having a thickness which is a small odd multiple of $\frac{1}{4}$ wavelength of light of predetermined wavelength.

5. A process as claimed in any of the

Claims 1 to 4, according to which the solution prior to being supersaturated, is 40 saturated with silica.

6. A process as claimed in Claim 5, according to which the solution is supersaturated with silica by adding a small amount of boric acid. 45

7. A process as claimed in Claim 5, according to which supersaturation is accomplished by diluting the saturated solution with water.

8. A process as claimed in Claim 5, 50 according to which supersaturation is accomplished by adding to the saturated solution a reagent which increases the amount of silica available for deposition.

9. A process as claimed in any of Claims 55 1 to 8, according to which a ceramic article, such as one having a glass surface, is immersed in a solution of fluosilicic acid having a concentration of 1.25 molar and which is supersaturated with respect to 60 silica to the extent of 2 to 16 millimoles of silica per litre of solution.

10. A process as claimed in any of Claims 1 to 9, according to which a glass article to be coated is immersed in a 65 solution of fluosilicic acid having a molar concentration of between 1.25 and 4 and which is at a temperature not exceeding 70° C., said solution being 8 to 16 millimoles of silica per litre of solution. 70

Dated this 18th day of August, 1947.
